Test of an Inverted J-Shape Hypothesis between the Expected Real Exchange Rate and Real Output: The Case of Ireland

Yu Hsing¹

Abstract

Applying an open-economy macroeconomic model, incorporating the monetary policy reaction function and uncovering interest parity, this paper finds that the expected real exchange rate and real output exhibit an inverted J-shape relationship, suggesting that expected real depreciation increases real output during 1999.Q2-2001.Q3 whereas expected real appreciation raises output during 2001.Q4-2009.Q1. Other findings show that a higher real financial stock price, a higher world real interest rate, or a lower expected inflation rate would increase real output. Fiscal prudence may be needed as the coefficient of the government borrowing/GDP ratio is insignificant at the 10% level.

Keywords: Expected Real Depreciation or Appreciation, Monetary Policy Reaction Function, Fiscal Policy, Financial Stock Price, Uncovered Interest Parity

JEL classification: E52, F31, F41, O52

1. Introduction

Known as the Celtic Tiger for more than a decade, Ireland had enjoyed rapid economic growth, budget surpluses, low inflation, low unemployment, and other positive developments. However, since 2008 Ireland's economy has been hit hard by the global financial crisis and world economic recession. According to the International Monetary Fund (2009), Ireland was faced with high dependence on construction, overvaluation of housing prices, over expansion of the banking sector, global competitive disadvantages, falling international market shares, high unit labor costs, declining share of FDI, risks associated with falling inflation, vulnerability in the financial sector, low interest margins, lack of growth in deposits, concentration of loan portfolios in residential mortgages, commercial properties, and real estate developments, and other challenges. According to the forecast for Ireland in 2009 made by the Economist (2009), its real GDP would suffer a decline of 7.7%, the government would have a budget deficit of 12.9% of GDP, and the current account balance would have a deficit of 3.1%. The short-term interest rate would drop to 1.4% from 4.6% in 2008. Due to a weak demand, the inflation rate would decline 3.6%.

This paper attempts to examine the roles of the expected real exchange rate and other related macroeconomic variables affecting output fluctuations. First, it incorporates

¹. Professor of Economics, Department of Business Administration & Finance, College of Business, Southeastern Louisiana University, Hammond, Louisiana 70403, USA. email: yhsing@selu.edu
the monetary policy reaction function in the formulation of the model. It is appropriate as the central bank of Ireland determines its short-term interest rate based on an inflation targeting of less than 2%. Second, the paper examines whether expected real depreciation or appreciation and real output may exhibit different relationships over time. The dummy variable technique will be employed to test if the intercept and/or the slope of the expected real exchange rate may have changed. Third, comparative static analysis will be applied in order to determine the possible response of equilibrium real GDP to a change in one of the exogenous variables.

There are several major studies examining the impact of currency depreciation or devaluation on output. Krugman and Taylor (1978) state that one of the conditions for currency devaluation to have a contractionary impact is whether exports are initially less than imports. Edwards (1986), Upadhyaya (1999), Bahmani-Oskooee, Chomsisengphet, Kandil (2002) and Christopoulos (2004) find that currency devaluation or depreciation could have a contractionary, an expansionary, or no effect depending upon the countries or time periods in empirical work. Chou and Chao (2001) and Bahmani-Oskooee and Kutan (2008) indicate that depreciation or devaluation is ineffective or has little impact in the long run.

These previous studies have made significant contributions to the understanding of the subject. These findings suggest that the impact of real depreciation could be expansionary, contractionary, or neutral and depends on the countries, time periods, specifications of a model, and methodologies employed in empirical work. To the author’s best knowledge, few of the previous studies have focused on the hypothesis that the impact of the real exchange rate on real output may exhibit an inverted J-shape relationship during different time periods.

2. The Model

Suppose that aggregate expenditures are a function of real output, domestic real interest rate, real government spending, real government tax revenues, real financial stock price, and real exchange rate. Also, suppose that real interest rate is determined by the inflation rate, real output, the real exchange rate, and the world real interest rate, that real exchange rate is affected by the domestic real interest rate, the world real interest rate, and the expected real exchange rate, and suppose that inflation rate is determined by the expected inflation rate, the output gap, and real exchange rate. Applying and extending Taylor (1993; 1995), Romer (2000; 2006), Svensson (2000), and other previous studies, we can express the open-economy IS function, the monetary policy reaction function, uncovered interest parity, and the augmented aggregate supply function as:

\[ Y = X(Y, R, G, T, W, \varepsilon) \]
Test of an Inverted J-Shape Hypothesis between the Expected Real Exchange Rate and Real Output: The Case of Ireland

\[ R = Z(\pi, Y, \varepsilon, R') \]  
\[ \varepsilon = E(R, R', \varepsilon^e) \]  
\[ \pi = \pi^e + \delta_1(Y - Y^*) + \delta_2 \varepsilon \]  

where

- \( Y \) = real GDP in Ireland,
- \( R \) = the domestic real interest rate,
- \( G \) = government spending,
- \( T \) = government tax revenues,
- \( W \) = the real financial stock price,
- \( \varepsilon \) = the real exchange rate measured as the euro per U.S. dollar times the relative prices in the U.S. and the EU (An increase means real depreciation of the euro),
- \( \pi \) = the inflation rate,
- \( R' \) = the world real interest rate,
- \( \varepsilon^e \) = the expected real exchange rate,
- \( \pi^e \) = the expected inflation rate,
- \( Y^* \) = potential output for Ireland, and
- \( \delta_1, \delta_2 \) = parameters.

Solving for four endogenous variables \( Y, R, \varepsilon, \) and \( \pi \) simultaneously, we can express equilibrium real GDP as:

\[ \bar{Y} = \bar{Y}(\varepsilon^e, G, T, W, R', \pi^e; \delta_1, \delta_2, Y^*). \]  

The Jacobian for the endogenous variables is given by:

\[ |J| = (1 - X_Y) - E_RW \varepsilon_Z Y - X_R Z_Y - E_{RZ} \varepsilon (1 - X_Y) \\
- Z_{\pi} [\delta_2 E_R (1 - X_Y) + \delta_1 X_R + \delta_1 E_{RZ} \varepsilon] > 0. \]  

We expect that the sign of \( \partial \bar{Y} / \partial G - \partial \bar{Y} / \partial T \) or \( \partial \bar{Y} / \partial W \) is positive. The effect of depreciation of the expected real exchange rate on equilibrium real GDP is unclear because the positive impact of increased net exports may be less or greater than the negative impacts of a higher inflation rate and a higher real interest rate due to monetary tightening:

\[ \partial \bar{Y} / \partial \varepsilon^e = E_{\varepsilon^e} Z_{\varepsilon^e} + X_R Z_{\pi} + \delta_2 X_R Z_{\pi} |J| > 0 \text{ or } < 0. \]  

Spencer and Kulkarni (2010) and McKinlay and Kulkarni (2010) study the J-curve hypothesis for four Central American countries and five African countries and show that multiple or consistent devaluations of a currency would shift the J-curve rightward and continuously deteriorate the trade balance.

The effect of a higher world real interest rate on equilibrium real GDP is ambiguous as the first term in the parenthesis in (8) is positive whereas the remaining terms in the parenthesis in (8) are negative:
Yu Hsing

\[
\frac{\partial Y}{\partial R} = (E_R X_e + E_R X_R Z_e + E_R X_e Z_R + X_R Z_R + \delta E_R X_R Z_e) / |J| > 0.
\]

A higher expected inflation rate would cause equilibrium real GDP to decline partly because the central bank would raise the real interest rate to contain inflation and partly because a higher real interest rate would cause real appreciation and reduce net exports:

\[
\frac{\partial Y}{\partial \pi^e} = (E_R X_e Z_\pi + X_R Z_\pi) / |J| < 0.
\]

3. Empirical Results

The data were collected from the International Financial Statistics (IFS), which is published by the International Monetary Fund. Real GDP is an index number with 2005 as the basis year. The real exchange rate is represented by the units of the euro per U.S. dollar times the relative prices in the U.S. and the EU. Thus, an increase means real depreciation of the euro, and vice versa. The expected real exchange rate is represented by the lagged real exchange rate. The simple lagged value is selected in order to have as many observations as possible to capture the relationship between the expected real exchange rate and real output. Due to lack of complete data for budget deficits, the ratio of government borrowing to nominal GDP is selected to represent fiscal policy. Both government borrowing and nominal GDP are measured in billions. The share price index is divided by the consumer price index to derive the real stock price index. The world real interest rate is represented by the refinancing rate of the European Central Bank (ECB) minus the inflation rate in the EU. The inflation rate is the percent change in the harmonized consumer price index in Ireland. The expected inflation rate is the lagged inflation rate. Except for the dummy variable, the real refinancing interest rate, and the expected inflation rate with zero or negative values, all other variables are measured in the log scale. The sample ranges from 1999.Q2-2009.Q1 with a total of 40 observations. The quarterly data for the refinancing rate beyond 2009.Q1 were not available.

The relationship between the expected real exchange rate and real GDP is presented in Graph 1. It seems that the relationship is nonlinear and exhibits an inverted J-shape. In other words, they have a positive relationship during 1999.Q2-2001.Q3 and a negative relationship during 2001.Q4-2009.Q1. Therefore, a dummy variable is generated with a value of 0 during 1999.Q2-2001.Q3 and 1 otherwise. An interactive dummy variable is also generated to test whether the slope coefficient of the expected real exchange rate may have changed.

Graph 1: Scatter Diagram between the Expected Real Exchange Rate and Real GDP: 1999.Q2-2009.Q1

Estimated parameters, standard errors, t-statistics, and other related information are presented in Table 1. Because a reduced form equation is estimated, endogeneity would not pose a concern. The Newey-West method is applied in order to yield consistent estimates for the covariance and standard errors. As shown, 92.8% of the behavior of real GDP can be explained by the right-hand side variables with significant coefficients. Except for the coefficient of ratio of government borrowing to GDP, all other coefficients are significant at the 1% or 5% level. Real GDP is positively associated with the intercept dummy variable, the real exchange rate, the real stock price and the real refinancing rate set by the ECB and negatively influenced by the interactive variable \( DUM \times \log(\varepsilon^e) \) and the expected inflation rate. The coefficient of the expected real exchange rate is estimated to be 0.550 during 1999.Q2-2001.Q3 and -0.536 (=0.550-1.086) during 2001.Q4-2009.Q1.

Notes:
The Dependent Variable is Log(Y).
Q4-2009.Q1.
$\epsilon^e$ is the expected real exchange rate defined as the lagged value of the units of the euro per
U.S. dollar times the relative prices in the U.S. and the EU.
BY is the ratio of government borrowing to GDP.
W is the real stock price index.
$R'$ is the real refinancing rate set by the European Central Bank (ECB).
$\pi^e$ is the expected inflation rate.
AIC is the Akaike information criterion.
SC is the Schwarz criterion.
MAPE is the means absolute percent error.

To determine whether these time series in Table 1 are cointegrated, the ADF unit root
test on the regression residuals $e_t$ is performed. The lag length of one is selected based on
the AIC. In the regression $\Delta e_t = \alpha e_{t-1} + \beta \Delta e_{t-1}$, the test statistic is estimated to be -2.044,
and the critical value is -1.950 at the 5% level. Hence, these variables have a long-run equilibrium relationship.

Several different versions are tested. When the intercept and interactive dummy variables are not included in the estimated regression, the adjusted $R^2$ is estimated to be 0.589, the coefficient of the expected real exchange rate is negative and significant at the 1% level, and the positive coefficient of the real refinancing rate is insignificant at the 10% level. This result may be misleading as the positive portion of the relationship is overlooked. When the ECB’s refinancing rate is replaced by the U.S. real federal funds rate, its coefficient is positive and significant at the 5% level. When both interest rates are included, their coefficients become insignificant at the 10% level mainly due to a high degree of multicollinearity. When the expected inflation rate is represented by average inflation rate of the past four quarters, its coefficient is positive and insignificant at the 10% level. To save space, these results are not printed here and will be made available upon request.

There are several comments. The inverted J-shape relationship between the expected real exchange rate and real GDP suggests that the recent trend of real appreciation of the euro against the U.S. dollar would work in favor of Ireland due to its positive impact on real output. The insignificant coefficient of the ratio of government borrowing to GDP implies that the Ricardian equivalence hypothesis (Barro, 1989) may apply and that expansionary fiscal policy may be pursued with caution as it may not be effective in raising real output. As the stock market has shown a rising trend, the wealth effect and the balance-sheet effect of a higher stock price would increase household consumption and business investment. It would be desirable for the central bank of Ireland to maintain transparency and effective communications in order to reduce inflationary expectations.

4. Summary and Conclusions

This paper examined the impacts of expected real depreciation or appreciation and changes in other related variables on output fluctuations in Ireland based on a simultaneous equation model incorporating the open-economy IS function, the monetary policy reaction function, uncovered interest parity, and an augmented aggregate supply. Real GDP is postulated to be a function of the dummy variable, the expected real exchange rate, the interactive dummy variable with the expected real exchange rate, the ratio of government borrowing to GDP, the real financial stock price, the real refinancing rate of the ECB, and the expected inflation rate. A generalized least squares method is employed in empirical work to yield consistent estimates for the covariance and standard errors.

There is evidence of an inverted J-shape relationship between the expected real exchange rate and real output, suggesting that expected real depreciation would increase real output up to 2001.Q3 whereas expected real appreciation would raise real output after 2001.Q3. Besides, a higher real stock price index, a higher refinancing rate, or a lower expected inflation rate would help raise real output. Expansionary fiscal policy represented by a higher ratio of government borrowing to GDP is found to be insignificant.

There may be areas for future study. The quadratic function may be applied to test the nonlinear relationship between the expected real exchange rate and real output. If the data are available, the ratio of government deficit to GDP can be selected to represent fiscal policy. Other macroeconomic theories such as the IS/LM model may be considered.
